

Dewlap color variation in *Anolis sagrei* is maintained among habitats within islands of the West Indies

Abstract

Animal signals evolve in an ecological context. Locally adapting animal sexual signals can be especially important for initiating or reinforcing reproductive isolation during the early stages of speciation. Previous studies have demonstrated that dewlap color in *Anolis* lizards can be highly variable between populations in relation to both biotic and abiotic adaptive drivers at relatively large geographical scales. Here, we investigated differentiation of dewlap coloration among habitat types at a small spatial scale, within multiple islands of the West Indies, to test the hypothesis that similar local adaptive processes occur over smaller spatial scales. We explored variation in dewlap coloration in the most widespread species of anole, *Anolis sagrei*, across three characteristic habitats spanning the Bahamas and the Cayman Islands, namely beach scrub, primary coppice forest and mangrove forest. Using reflectance spectrometry paired with supervised machine learning, we found significant differences in spectral properties of the dewlap between habitats within small islands, sometimes over very short distances. Passive divergence in dewlap phenotype associated with isolation-by-distance did not seem to explain our results. On the other hand, these habitat-specific dewlap differences varied in magnitude and direction across islands, and thus our primary test for adaptation – parallel responses across islands – was not supported. We suggest that neutral processes or selection could be involved in several ways, including sexual selection. Our results shed new light on the scale at which signal color polymorphism can be maintained in the presence of gene flow, and the relative role of local adaptation and other processes in driving these patterns of dewlap color variation across islands.

Keywords — reflectance, adaptation, sexual signal, machine learning, polymorphism

Introduction

The staggering diversity of animal communication signals has long been of interest to evolutionary biologists. Animals use chemical, mechanical, electromagnetic, and visual signals to communicate in a wide variety of contexts, including, competition for mates, species recognition, aposematism, and cooperation (Bradbury and Vehrenamp, 2011). A primary evolutionary factor shaping communication signals is the sensory system and behavior of recipients (the sensory drive hypothesis; Endler and McLellan 1988; Endler 1992, 1998). Over the past decades, scientists have established that signals evolve in an ecological context and are dependent on environmental conditions (Endler, 1992, 1993a,b). Just as different habitats may favor different combinations of ecomorphological traits to maximize performance and fitness (Arnold, 1983), they may also shape different forms of a signal, so as to maximize its transmission and detection (e.g. Seehausen 1997), or reduce its detection by unintended recipients such as predators (Endler, 1984, 1990, 1991; Halfwerk et al., 2014). This selective pressure may drive the local adaptation of communication signals.

One potential barrier to the maintenance of localized signal divergence is the homogenizing effect of gene flow. Population genetics theory suggests that gene flow may counteract local adaptation between localities and prevent divergence altogether, especially at small spatial scales, because of the inflow of maladapted alleles or because of the breaking of linkage between coevolving loci (Felsenstein, 1976; García-Ramos and Kirkpatrick, 1997; Dieckmann and Doebeli, 1999; Lenormand, 2002; Hendry et al., 2007a). This genetic homogenization has been confirmed empirically in systems such as stick insects (Nosil and Crespi, 2004) and stickleback (Hendry et al., 2007b). Yet, examples of microgeographic adaptation, i.e. adaptation at smaller scales than the range of dispersal, exist, highlighting the potential of some organisms to respond to selection in the face of

gene flow (see Richardson et al. 2014 and references therein). Examples include small scale adaptation in fragmented areas in Australian fruit flies (Willi and Hoffmann, 2012), and local adaptation to predation pressure in North American salamanders (Richardson and Urban, 2013). Therefore, despite evidence that local adaptation may be particularly difficult at small spatial scales where gene flow tends to cause adjoining populations to remain genetically homogeneous, the potential adaptive response of species traits, in particular communication signals, to localized differences in habitats remains relatively unknown (Richardson et al., 2014). Lizards of the neotropical genus *Anolis* are an excellent group for studying the eco-evolutionary dynamics of local adaptation and natural selection (Losos, 2009). A particularly conspicuous trait of anoles is their dewlap, an extensible flap of skin that is typically sexually dimorphic and used as a communication signal in courtship (Sigmund, 1983; Driessens et al., 2014, 2015) and territorial displays (Losos, 1985; Macedonia and Stamps, 1994; Macedonia et al., 2013) as well as in predator deterrence (Leal and Rodríguez-Robles, 1995, 1997; Leal and Rodriguez-Robles, 1997). Dewlap characteristics vary widely among the approximately 400 species of the genus (Nicholson et al., 2007). Interspecific variation in dewlap coloration is implicated in species recognition (Rand and Williams, 1970; Williams, 1969; Williams and Rand, 1977; Losos, 1985; Macedonia and Stamps, 1994; Fleishman, 2000; Macedonia et al., 2013), and this function could have had a role in initiating or reinforcing reproductive isolation during speciation (Lambert et al., 2013; Geneva et al., 2015; Ng et al., 2017).

Within species, studies have shown a link between variation in dewlap coloration and differences in habitats or climatic conditions (Macedonia, 2001; Leal and Fleishman, 2002; Thorpe and Stenson, 2002; Thorpe, 2002; Leal and Fleishman, 2004; Vanhooydonck et al., 2009; Ng et al., 2012, 2013, 2016; Vanhooydonck et al., 2009; Driessens et al., 2017). Some studies suggest that those differences may be adaptive and that dewlaps may have evolved to maximize detectability given local light conditions (Fleishman and Persons, 2001; Leal and Fleishman, 2002, 2004). Although this claim is further supported by recent findings that dewlap colors are perceived differently under different levels of shading (Fleishman et al., 2020), other studies found conflicting patterns of between-habitat variation that did not support the sensory drive hypothesis (Fleishman et al., 2009; Ng et al., 2012; Macedonia et al., 2014).

Previous studies investigating variation in anole dewlaps compared populations at relatively large geographical scales, e.g. between islands (Vanhooydonck et al., 2009; Driessens et al., 2017) or within large islands such as Puerto Rico (Leal and Fleishman, 2004) or Hispaniola (Ng et al., 2012, 2016). These large scales and marine barriers should reduce gene flow (Ng and Glor, 2011; Lambert et al., 2013; Richardson et al., 2014; Ng et al., 2017). That said, examples do exist of divergence in dewlap coloration at smaller scales or between populations with high degrees of gene flow (Thorpe and Stenson, 2002; Thorpe, 2002; Stapley et al., 2011; Ng et al., 2016).

Anolis sagrei is widespread across islands of the West Indies (Reynolds et al., 2020). It has been the subject of numerous studies concerning local adaptation (Losos et al., 1994, 1997, 2001; Kolbe et al., 2012), biological invasion (Kolbe et al., 2008), and sexual selection (Tokarz, 2002; Tokarz et al., 2005; Tokarz, 2006; Driessens et al., 2014; Steffen and Guyer, 2014; Driessens et al., 2015) among many other topics. Between-island variation in the mainly orange-red color of its dewlap was shown to be better explained by climatic variables such as annual precipitation and solar radiation (proposed to affect the average vegetation type on each island and among other things, its ambient light environment, Driessens et al. 2017), than by proxies for biotic factors such as sexual selection or predation pressure (Vanhooydonck et al., 2009; Baeckens et al., 2018). How intra-island differences in habitat may contribute to the diversity of dewlap coloration, however, remains unexplored, and may reveal new insights into the scale of local differentiation despite gene flow.

Here, we analyzed the color characteristics of *A. sagrei* dewlaps within nine islands in the Bahamas and Cayman Islands. These island systems presently, if not historically, comprise relatively small islands, with no major geographic barriers within islands limiting dispersal for this species (Kamath and Losos, 2018). These islands all share three characteristic native West Indian small-island habitat-types – beach scrub bush, closed-canopy primary coppice forest, and mangrove forest – that are often spatially intermingled. These habitats contrast in environmental parameters including vegetation community, light irradiance, humidity, and temperature (Howard, 1950;

Schoener, 1968). The Cayman Islands and the Bahamas have been colonized independently by *A. sagrei* from Cuba (van de Schoot 2016 unpublished thesis; Reynolds et al. 2020), such that these archipelagos constitute an ideal suite of natural replicates to explore within-island dewlap diversity across multiple islands. 107

Our sampling design included sites in close proximity; the median distance between two sites within an island was 11.2km. While this species has traditionally been considered territorial, recent study reveals that they are polygynandrous and that gene flow is not impeded by territorial-like behaviors exhibited by some males (Kamath and Losos 2018). Combining reflectance spectrometry and supervised machine learning, we tested for divergence in dewlap phenotype between habitats within islands and between islands across part of the range of *A. sagrei*. We predicted that if light conditions in the environment indeed drive color evolution, dewlaps should be most similar between beach scrub and mangrove forest, which both have high levels of light irradiance, compared to the darker, closed-canopy coppice forest. If detectability is maximized given the local conditions, we expected darker and more contrasting dewlaps in high irradiance habitats. Finally, if habitat characteristics are strong determinants of dewlap color variation, similar patterns should be observed across multiple islands (Harvey and Pagel, 1991; Losos, 2011). 111

124 **Methods**

125 **Data collection**

126 We sampled 466 male *A. sagrei* from seven islands in the Bahamas Archipelago – Abaco, North
127 Andros, South Andros, South Bimini, Eleuthera, Long Island, and Ragged Island – and two in the
128 Cayman Islands – Cayman Brac and Little Cayman (Figure S1A). These islands were chosen to
129 span the breadth of the West Indian range of *A. sagrei*, because they have highly similar habitat
130 types, and because the *A. sagrei* on each island group are derived from ancient and distinct
131 colonization events from Cuba (i.e. relatively evolutionarily independent, Reynolds et al. 2020).
132 Three habitats were sampled on each island based on characterizations by Howard (1950) and
133 Schoener (1968). Each habitat is clearly distinguishable by its dominant vegetation type — xeric
134 beach scrub (open, relatively dry habitat consisting of low vegetation or isolated trees), primary
135 coppice forest (closed-canopy forest) and mangrove forest (wet coastal habitat with trees growing
136 in brackish water and high light penetration, although lizards were sampled in dry soil areas).
137 Sample sizes are given in Table S1. Our sampling design enabled us to test for differences between
138 habitats at a coarse and fine geographical scale. The median distance between two localities within
139 an island was ~ 11km (Figure S1B), and 80.3% of all pairwise distances within islands were less
140 than 50km. Additionally, there are no major barriers to dispersal (such as mountains or grassland)
141 on any of the islands that we sampled.

142 **Reflectance measurements**

143 We measured reflectance between 300nm and 700nm wavelength, a range from ultraviolet to red
144 that encompasses the colors visible to most lizards and vertebrates in general (Lazareva et al.,
145 2012). Measurements were taken with an Ocean Optics USB4000 spectrometer, a pulsed Xenon
146 light source (PX-2, Ocean Optics, Largo, FL, USA) and a reflectance probe protected by a black
147 anodized aluminum sheath. Measurements were taken with a 45-degree inclination to prevent
148 specular reflection (Endler, 1990). The device was regularly standardized with a Spectralon white
149 standard (Labsphere, North Sutton, NH, USA). Reflectance was measured at the center of the
150 dewlap. Reflectance curves were smoothed using the R package pavo (Maia et al., 2013) as well
151 as with custom R functions, down to one reflectance value at each nanometer in wavelength from
152 300 to 700nm.

153 **Analysis**

154 We tested for detectable differences in dewlap coloration between populations from different habi-
155 tats across islands by following an analytic pipeline in several steps. First, we used multivariate
156 analyses of variance to assess the relative contributions of islands, habitats and habitat-by-island
157 interactions on the partitioning of variation in color space. Second, and provided that habitat-by-
158 island interactions were found, we investigated habitat-differences in dewlap color for each island
159 separately using machine learning classification. Third, for each island where multivariate differ-
160 ences were detected using our machine learning pipeline, we used univariate analyses of variance
161 to decompose the signal among the different dimensions of color space. Fourth, for each signifi-
162 cant between-habitat variation found in univariate analyses, we used post-hoc tests to determine
163 which habitats were responsible for the differences. Last, to get insights into the spatial scale of
164 phenotypic variation, for each significant contrast between two habitats detected along a given
165 dimension on a given island, we performed multiple pairwise Wilcoxon tests to assess differences
166 in dewlap coloration among the sites involved in that significant contrast, and recorded the geo-
167 graphical distance between sites that were found significant. In parallel, we tested a possible effect
168 of isolation-by-distance, an alternative cause of phenotypic divergence between localities, based on
169 diffusion approximation and dispersal distance, irrespective of habitat types. We did so using a
170 permutation test to assess the significance of the correlation between geographical distances and
171 phenotypic distances among sites within each island.

172

173 All analyses in this study were performed in R 3.6.1 (R Core Team, 2019).

Dimensionality reduction

174

Because neighboring wavelengths are highly collinear and redundant in reflectance, we reduced the dimensionality of the data using principal component analysis (PCA), as per Cuthill et al. (1999) and Leal and Fleishman (2002). We performed PCA on data from all islands combined, as well as on each island separately and systematically retained the first four principal components (PC), which together always explained more than 88.8% of the variance across islands (Table S2). PCs need not represent the same wavelengths across islands because they are fitted on different datasets. Nevertheless, PC1 was highly collinear with brightness for all islands (Figure S11), while the other PCs captured the chromatic variation (i.e. irrespective of brightness) in dewlap color.

Among-island variance partitioning

183

We performed a two-way nonparametric multivariate analysis of variance (PERMANOVA, Anderson 2001, R package vegan, Oksanen et al. 2019) to identify differences in coloration between islands, habitats and habitats within islands, using principal components fitted on data from all islands together. We used a nonparametric test because although no multivariate outliers were detected based on the Mahalanobis distance, the assumption of multivariate normality was violated in several habitats on several islands (Henze-Zirkler's test, Henze and Zirkler 1990, R package MVN, Korkmaz et al. 2014, $P < 0.05$, Table S3).

Within-island machine learning

191

We performed a machine learning classification analysis on the first four principal components within each island separately, using random forests (Breiman, 2001). Random forests are a versatile, intuitive, and powerful algorithm commonly used in machine learning, using decision trees to predict the labels of particular observations based on their multivariate coordinates. These coordinates, or variables, are passed through a series of successive decision nodes, each examining a given variable of any given observation (James et al., 2013). The prediction for each observation is an aggregate over a large number of decision trees, each tree being trained on a subset of observations sampled with replacement from the dataset, and each tree being allowed to examine only a subset of the variables. This allows the random forest to overcome the individual errors of all trees in the predictions it makes.

To detect differences in dewlap coloration between habitats, we measured the success of random forests in reassigning individual lizards to their correct habitat of origin, based solely on their principal component scores. In machine learning, this so-called cross-validation procedure is typically done in two steps (James et al., 2013). First, a random forest is trained in recognizing features of dewlap coloration most associated with the different habitats, by being presented with multiple observations, making predictions about them, and updating its own decision rules based on whether the prediction deviates from the truth. Then, once trained, the patterns that the random forest has learned to recognize are tested by presenting new, previously unseen observations to the random forest, and measuring the proportion of correct predictions. This proportion, or success score, can then be statistically assessed against random guessing using a binomial test.

The cross-validation procedure requires that the data be split into a training set and a testing set. To remove any bias due to the set that is being sampled for training, it is common practice to use k-fold cross-validation (James et al., 2013), where the data are split into k random bins and k independent machines are trained, each taking one of the bins as a testing set and the rest for training, and where classification success is measured by summing all correct classifications from the k machines.

Here, we used a k-fold cross-validation procedure with $k = 5$, where each training set consisted of 80% of the data and the machine was tested on the remaining 20%. Each training set was conditioned on containing at least five lizards from each of the three habitats. We also down-sampled the training set to the sample size of the least represented habitat, to ensure that the different habitats were equally represented. To further remove any bias due to the specific random split into the different bins, we replicated each k-fold cross-validation five times. We then averaged the five resulting confusion matrices across replicates, where each confusion matrix shows the number

of lizards from each habitat reassigned into each habitat. For each island, we then used the average proportion of correctly reassigned lizards (i.e. the proportion of observations on the diagonal of the average confusion matrix) as an estimate of classification success. This score was tested against random guessing by comparing it to a binomial distribution with number of trials being the number of lizards on that island and success probability 1/3, representing the rate of successful classification by chance when three habitats are involved.

We used the machine learning fitting functions in the R package rminer (Cortez, 2020), which calls random forest routines from the randomForest package (Liaw and Wiener 2002, implementation from the original random forest algorithm Breiman, 2001). For each random forest, we optimized the number of trees in the forest and the number of variables examined by each tree using the grid hyperparameter search procedure implemented in rminer, to choose between two numbers of trees (500 or 1,000) and four numbers of principal components examined per tree (1 to 4), using rminer's ordered holdout validation method with 2/3 of the data used for training.

We validated the results of our analysis by using two other widely used machine learning classification methods: linear discriminant analysis and support vector machines (Cristianini and Shawe-Taylor, 2000; James et al., 2013), both accessible in rminer (Cortez, 2020).

To know which wavelengths were most used to assign data points to each habitat, we trained another set of random forests, this time directly on reflectance data (taken every 5nm from 300 to 700nm) instead of principal components. We recorded the relative importance of each wavelength for each habitat, as measured by the mean decrease in accuracy during wavelength permutation, implemented in the randomForest package (Liaw and Wiener, 2002).

Univariate analyses

For each island where significant differences in dewlap coloration were detected between habitats, we used multiple univariate analyses of variance (ANOVA) to identify possible principal components underlying the observed differences. We constructed our ANOVA models in two steps, as per Zuur (2009). In a first step, we accounted for heterogeneity of variances across groups by systematically comparing the goodness-of-fit of an ANOVA model estimated with ordinary least squares (OLS) with that of a model estimated with generalized least squares (GLS), which allowed one estimate of residual variance per habitat (using the R package nlme, Pinheiro and Bates 2000; Pinheiro et al. 2020). Both models were fitted with restricted maximum likelihood (REML). Goodness-of-fit was estimated using Akaike's Information Criterion corrected for small sample sizes (AICc, R package MuMIn, Bartoń 2019), and the estimation method yielding the lowest AICc was retained. In a second step, we re-fitted the retained model with maximum likelihood (ML) to test for the effect of habitat type using likelihood ratio tests (LRT) between a model including a habitat-term and a null model lacking the habitat-term.

We evaluated the normality of the standardized residuals (residuals divided by their standard error, which can differ among habitats in a GLS model) of each fitted ANOVA model using Shapiro-Wilk's test, with P-values adjusted for multiple testing using the Benjamini-Hochberg correction (Benjamini and Hochberg, 1995). In cases where significant deviations from normality were detected ($P_{adj} < 0.05$, Table S4) we performed Kruskal-Wallis's nonparametric test to back up the ANOVA results.

To know which habitat-populations were different from which in dewlap coloration, we performed different post-hoc multiple comparison tests (all implemented in the PMCMRplus package, Pohlert, 2020), depending on which assumptions were met. In cases where normality and homoscedasticity were met (i.e. OLS-ANOVA was the best fit), we used Tukey's honest significant difference test. When normality was met but not homoscedasticity (i.e. GLS-ANOVA was the best fit), we used Dunnett's T3 test. Finally, whenever we used Kruskal-Wallis's test because the ANOVA residuals were not normally distributed, we used Nemenyi's test for post-hoc comparisons.

Spatial autocorrelation

281

We tested for within-island spatial autocorrelation between the geographical distances among sampling sites and their Euclidean distances in multivariate color space (mean PC1 to PC4 per site, Table S5), regardless of habitat type. For this, we performed Mantel's test (Legendre and Legendre 2012, R package vegan; Oksanen et al. 2019) on each island, using 999 permutations and geographical distances computed as geodesic distances from latitude and longitude data (R package geosphere, Hijmans 2019).

Site differences

289

In this study, we were interested in the minimum spatial scale at which significant differences between habitats could be detected within islands. We performed multiple pairwise nonparametric Wilcoxon-Mann-Whitney tests (Hollander et al., 2013) to compare dewlap coloration between sites with different habitat types, for each pair of habitats and each variable where significant differences were detected with our analyses of variance. The P-values were adjusted using a Benjamini-Hochberg correction for multiple testing (Benjamini and Hochberg, 1995).

295

296 **Results**

297 We tested for variation in *A. sagrei* dewlap coloration between populations living in three charac-
298 teristic habitat types across nine islands that span the West Indian range of the brown anole (beach
299 scrub, primary coppice and mangroves). We found that most of the variation in coloration was
300 partitioned between islands (two-way PERMANOVA, $F(df = 8) = 43.7$, $P = 0.0001$, explained
301 variance $R^2 = 40.9\%$). Nonetheless, we did find evidence for differences in dewlap coloration
302 between habitat types, and those were mostly island-specific (habitat-by-island interaction term,
303 $F(16) = 3.53$, $P = 0.0001$, $R^2 = 6.6\%$), with a significant portion of the variation explained by
304 an habitat effect across all islands, but this effect was relatively small ($F(2) = 4.7$, $P = 0.0001$,
305 $R^2 = 1.1\%$).

306

307 We subsequently tested for differences in dewlap coloration between habitat-populations within
308 each island, using within-island principal component scores (to maximize the variation captured
309 for each island, see Methods). Our within-island random forest classification analyses revealed
310 detectable differences in dewlap coloration on eight out of the nine islands in our sample: Abaco,
311 Bimini, Cayman Brac, Eleuthera, Little Cayman, Long Island, North Andros and South Andros.
312 The accuracy of random forest classification exceeded random expectation more often than ex-
313 pected by chance for all these islands (Table 1). Accuracy was as high as 73% for Cayman Brac.
314 We obtained similar results using other machine learning approaches such as support vector ma-
315 chines (Table S7) and linear discriminant analysis (Table S8), except that these methods did not
316 detect significant differences on Eleuthera and North Andros. We describe in details the specific
317 differences detected on each island in the Appendix, and focus here on the general patterns emerg-
318 ing from our data.

319

320 Overall, we found significant differences in dewlap coloration between populations that were
321 often in close geographical proximity. On Bimini, notably, we found a significant difference be-
322 tween dewlaps from beach scrub and primary coppice forest, at a distance of a few hundred meters,
323 making this contrast the smallest geographical scale at which differences in coloration were found
324 in our study (Fig. S3). We also detected significant differences in dewlap coloration at distances
325 below one kilometer on Abaco (Fig. S2G), and at distances between one and ten kilometers on
326 Bimini (Fig. S3G), Cayman Brac (Fig. S4G), Little Cayman (Fig. S6G), Long Island (Fig. S7G)
327 and South Andros (Fig. S10G).

328

329 We found evidence of spatial autocorrelation in dewlap coloration between the sites within is-
330 lands for Abaco (Table 2), suggesting that populations from closer sites tend to have more similar
331 dewlaps on this island than expected by chance. Abaco was the island we sampled at the largest
332 scale, with some sites nearly a hundred kilometers away from each other (Fig. 2A). That said, some
333 sites were also in close proximity, and significant differences in coloration were detected between
334 habitats sometimes less than a kilometer away (Fig. S2G), suggesting that differences in dewlap
335 coloration between distant sites may be partly attributable to isolation-by-distance, but this may
336 not necessarily be the case for sites in close proximity. We did not find evidence for spatial auto-
337 correlation on other islands than Abaco (although Eleuthera was nearly significant, Table 2).

338

339 A striking feature of our data was inconsistencies in between-habitat differences among is-
340 lands, in terms of which habitats differ from which, which dimensions of coloration were involved,
341 and in which direction. For example, while on Cayman Brac the random forests could well dis-
342 tinguish between all three habitats (Fig. S4D), on Abaco dewlaps from beach scrub and primary
343 coppice were often mistaken, and on Bimini beach scrub dewlaps were more often classified into
344 primary coppice or mangrove than into beach scrub (Fig. S3D). In terms of variable importance,
345 for multiple islands the random forests used information in the UV range to discriminate between
346 at least some habitats, particularly on Abaco (Fig. S2F), Bimini (Fig. S3F), Cayman Brac (Fig.
347 S4F), Little Cayman (Fig. S6F) and Long Island (Fig. S7F), but differences in UV reflectance
348 involved different habitats and were in different directions among these islands.

349

Discussion

Two main insights follow from our results. First, we detected significant differences in dewlap coloration between habitats within seven out of the nine islands investigated (excluding North Andros where the follow-up univariate analyses were not significant), suggesting a putatively high potential for local differentiation of dewlap coloration in *Anolis sagrei*. Second, we found differences in coloration along different dimensions of color space, and in different directions, on different islands.

Detectable differences in dewlap color between populations are surprising, as habitats were often in close geographical proximity to each other (as close as a few hundred meters on Bimini and most of the time within ten kilometers). Indeed, given that (1) the populations were continuously distributed between the habitats, (2) populations from different habitats were not monophyletic with respect to mitochondrial haplotypes (van de Schoot 2016 unpublished thesis), and (3) *A. sagrei* is highly mobile (Kamath and Losos, 2018), we would have expected more homogeneous distributions of color phenotypes within islands due to gene flow, with fewer differences between populations, especially those in close proximity. , and we would have expected gene flow to cause a more homogeneous distribution of color phenotypes within islands. While little is known about the cruising range of individuals from our study populations (but see Kamath and Losos 2018; ?), *A. sagrei* are polygynandrous (where both males and females mate with multiple mates, Kamath and Losos 2018; ?), thus offering opportunity for gene flow, especially given that lizards were distributed continuously and at high densities within the islands we sampled. Consistent with that, while populations from different islands were monophyletic, individuals within islands were not monophyletic with respect to habitat based on mitochondrial haplotypes (van de Schoot 2016 unpublished thesis).

Several scenarios could account for these findings. One explanation is an adaptive one: populations living in different habitats could be phenotypically adapted to their local environmental conditions. Given that the brightly colored dewlap of *A. sagrei* is used as a communication signal, its color may be a target for selection if the transmission or perception of the signal differs from one habitat to another, for example because of differences in ambient light, according to the sensory-drive hypothesis (Endler and McLellan, 1988; Endler, 1992, 1998). The sensory-drive hypothesis has been tested multiple times for dewlap coloration in *Anolis* lizards, with mixed results. Some authors found support for it (Leal and Fleishman, 2002, 2004), while others found differences in dewlap coloration between habitats inconsistent with the sensory-drive hypothesis (Fleishman et al., 2009; Ng et al., 2012).

If our results were an example of sensory drive, we would have expected to see consistent differences between populations from different habitats across islands, given the apparent environmental consistency each of the three habitat types across the islands we sampled. In particular, we would have expected divergence in line with increased detectability given local light conditions, such as the high contrasts with background vegetation found in the UV range in Leal and Fleishman (2002) and Leal and Fleishman (2004). We might also have expected mangrove and beach scrub lizards, both inhabiting areas with high light penetration, to have more similar dewlaps, and to differ significantly from lizards from the coppice habitat, where irradiance is low. Instead, we found inconsistencies in the way dewlap color differed between habitats across islands. While short-wavelengths (UV reflectance) were often involved in color differences, they were not involved on all islands where significant differences were detected. On some islands, other or additional variables differed, such as brightness, red reflectance or the reflectance at the ends of the spectrum visible to *Anolis* lizards (UV and red, Lazareva et al. 2012) relative to intermediate wavelengths (blue-to-yellow). Similar portions of the spectrum were sometimes involved in opposite directions on different islands, such as on Abaco and Cayman Brac, where mangrove lizards had a higher UV-reflectance than beach scrub lizards on the former, but a lower UV-reflectance on the latter. Overall, the observed heterogeneity of divergence patterns across islands provides no support to a sensory-drive explanation.

It is presently not known if the reported differences in coloration have a genetic basis. Yet, we find it unlikely that these differences arose through phenotypic plasticity, as although the carotenoids that partly make up the red and orange colors of anole dewlaps must be found in

407 the diet (Goodwin, 1984; Hill et al., 2002; Hill and McGraw, 2006), studies testing the effect of
408 carotenoid deprivation (Steffen et al., 2010; Ng et al., 2013) and heritability (Cox et al., 2017) of
409 dewlap coloration in *A. sagrei* and *A. distichus* (another species with a carotenoid-based dewlap),
410 found little support for phenotypic and developmental plasticity in dewlap coloration. One excep-
411 tion is a study demonstrating that lizards heavily parasitized by skin mites had duller dewlaps
412 (Cook et al., 2013), but we found no sign of that in our study.

413

414 We found no evidence for a role of genetic drift in explaining the observed patterns either. First,
415 *A. sagrei* was distributed across the islands continuously, usually at relatively high population
416 densities, rather than in small and isolated populations where drift might be expected to have a
417 strong effect. Second, we found no evidence of isolation-by-distance except on Abaco, which was
418 sampled at the largest geographical scale, with sites nearly a hundred kilometers apart from each
419 other. Hence, while isolation-by-distance may explain long-range differences on this island, most of
420 the differences among habitats across the rest of the sampling region are unlikely to be explained
421 by genetic drift, as habitats were often in close proximity (less than 10km).

422

423 Genetic drift could contribute to some of the observed variation. Indeed, while only Abaco
424 showed significant patterns consistent with isolation-by-distance (which may emerge under limited
425 dispersal and drift, Wright 1943; Kimura and Weiss 1964; Slatkin 1987), there may have been
426 too few sites on most islands to conclusively detect it, and even then, the absence of detectable
427 isolation-by-distance may not necessarily constitute evidence for the absence of drift. Besides,
428 spatial autocorrelation was the strongest on islands sampled at the largest scales (e.g. some sites
429 on Abaco were nearly 100km apart, and Eleuthera – the second strongest signal, albeit nonsignif-
430 icant – had sites more than 30km apart), such that it is possible that neutral processes and/or
431 dispersal limitations might contribute to shaping variation over long distances. That said, many
432 significant differences were found between habitats in close proximity, contrary to what would be
433 expected under isolation-by-distance, including on islands where spatial autocorrelation was de-
434 tected. Moreover, *A. sagrei* was distributed across the islands continuously, usually at relatively
435 high population densities, rather than in small and isolated populations particularly prone to drift.
436 Together with the fact that isolation-by-distance may not necessarily only emerge from drift (e.g.
437 if there is a spatial environmental gradient), this indicates that genetic drift may have limited
438 potential to explain the differences observed between habitats, at least at a local scale.

439

440 In this study, we found larger differences among than within islands, a pattern already re-
441 ported and linked to climatic conditions (Driessens et al., 2017) and to densities of predators and
442 of anole congeners (Vanhooydonck et al., 2009; Baeckens et al., 2018). Differences among habi-
443 tats within islands, however, are still difficult to account for. Remaining hypotheses may include,
444 for example, runaway sexual selection (i.e. arbitrary preferences of females for some colors over
445 others, Andersson 1994) arbitrarily operating in different directions across islands, but no evi-
446 dence so far suggests that dewlap is a target of mate choice in anoles (Tokarz, 2002; Tokarz et al.,
447 2005; Lailvaux and Irschick, 2006; Nicholson et al., 2007). Another hypothesis is that the differ-
448 ent genetic constitutions of different islands, perhaps resulting from founder effects (the islands
449 have been colonized independently, van de Schoot 2016 unpubl.; Driessens et al. 2017; Reynolds
450 et al. 2020), may have predisposed populations to adapt differently to similarly selective circum-
451 stances. That said, signalling can be a multifaceted behavior, and while we focused on dewlap
452 color here, other potentially important elements of behavioral interactions include dewlap size,
453 dewlap patterning, display activity as well as behaviors associated with dewlap extensions such as
454 headbobs and pushups (Vanhooydonck et al., 2005; Driessens et al., 2014, 2015; Lailvaux et al.,
455 2015). These have been linked in various ways (and not always consistently across studies) not
456 only with environmental variables but also with proxies for sexual selection, predation and species
457 recognition (Vanhooydonck et al., 2005; Lailvaux and Irschick, 2007; Vanhooydonck et al., 2009;
458 Driessens et al., 2017; Baeckens et al., 2018), which do vary among islands but may also vary
459 within islands, possibly in interaction with dewlap color. Either way, new data would be needed
460 to test these hypotheses. Visual modeling, for instance, would be a valuable follow-up analysis as
461 it would indicate whether the differences we detected may be detectable by the organisms them-
462 selves (as has been done in *Anolis* in Leal and Fleishman 2004; Fleishman et al. 2020), but such
463 approach requires irradiance profiles from the habitats in the field, which we presently do not have.

464

Altogether, our results show that dewlap color of *A. sagrei* commonly varies between habitat types, even in close geographical proximity, within islands of the West Indies. However, coloration differs in different ways across similar habitats from one island to another. We discussed several non-mutually exclusive mechanisms that could explain these observations. Nevertheless, heterogeneous patterns of divergence across islands do not support an adaptive sensory-drive scenario, and we propose that within-island dewlap color variation may be underlain by a more subtle mosaic of factors.

Appendix

725

Here we describe more precisely the patterns identified on each island.

726

On Abaco, dewlaps from the mangrove habitat were the best discriminated, while dewlaps from the beach scrub habitat were often mistaken for dewlaps from the coppice habitat (Fig. 2D). Importance analysis revealed that beach scrub and mangrove lizards mostly differed in reflectance in the ultraviolet (UV) end of the spectrum (below 400nm, Fig. S2F), where mangrove dewlaps had higher UV reflectance relative to beach scrub lizards, and coppice lizards had an intermediate UV reflectance between the two other habitats (Fig. 2B). Consistent with this, our analyses of variance detected significantly lower PC2 scores in mangrove lizards than in the two other habitats (Fig. 2E, Table 3), representing a higher UV-reflectance relative to red (Fig. 2C). Beach scrub lizards also scored lower on PC3 (Fig. 2E, Table 3), indicating less curvature of the reflectance profile and relatively higher reflectance at intermediate wavelengths (blue-to-yellow) than at the ends of the range (Fig. 2C). Differences were detected between sites both at large ($\sim 100\text{km}$) and short ($< 1\text{km}$) distances (Fig. S2G). Abaco was the only island where we detected significant spatial autocorrelation (Table 2), that is, sites that were closer geographically tended to have populations of lizards with more similar dewlap colors.

781

On Bimini, the random forests mostly correctly classified lizards from the coppice and mangrove habitats while often misclassifying lizards from the beach scrub habitat (Fig. S3D). Relatively flat importance profiles for beach scrub lizards suggested that brightness was used instead of a particular wavelength to identify some of the beach scrub dewlaps (Fig. S3F). Indeed, some beach scrub dewlaps were substantially brighter than the rest (Fig. S3B, C), a pattern that was captured by our analysis of variance along PC1 (i.e. brightness, Fig. S3C, E, Table 3). The random forests also used UV reflectance to discriminate between coppice and mangrove dewlaps (Fig. S3F), which could reflect the significant difference we detected along PC3 between these two habitats (Fig. S3C, E, Table 3). Beach scrub lizards were characterized by elevated red reflectance relative to UV (as represented by PC2, (Fig. S3C, E)), and beach scrub and mangrove lizards were characterized by a more even distribution of the reflectance along the spectrum (as represented by PC3, (Fig. S3C, E)), in contrast to coppice lizards which harbored a stronger curvature at intermediate wavelengths (Fig. S3C, E). On this island, the beach scrub and coppice habitats were separated by a few hundred meters, making this contrast the smallest geographical scale at which differences in coloration were found in our study (Fig. S3G).

On Cayman Brac, all three habitats could be well discriminated against each other (Fig. S4D), with UV reflectance appearing to be an important variable differentiating beach scrub and mangrove dewlaps (Fig. S4F). In contrast, coppice dewlaps had a relatively flat importance profile, suggesting that brightness made them more distinct rather than any particular wavelength (Fig. S4F). Consistent with this, coppice dewlaps were significantly different from all other dewlaps along PC1 (Fig. S4E, Table 3). At a distance between 2 and 3km (Fig. S4G), dewlaps in the beach scrub habitat reflected more red light (as represented by PC2, Fig. S4C, E) and more UV (as represented by PC3, Fig. S4C, E) than in the mangrove habitat. Coppice lizards were also characterized by a higher UV reflectance than mangrove dewlaps (PC3, Fig. S4C, E, Table 3).

On Eleuthera, although random forests detected between-habitat differences in dewlap color, other approaches did not (Tables S8 and S7), suggesting that the differences may be small. Consistent with this, the only significant univariate difference detected was for PC2 between beach scrub and mangrove lizards, where beach scrub lizards had higher levels of red reflectance and mangrove lizards higher levels of UV reflectance (Fig. S5C, E, Table 3).

Little Cayman was characterized by a better discrimination of mangrove lizards from the rest than between beach scrub and coppice lizards (Fig. S6D). Mangrove dewlaps were most distinct with respect to their reflectance in short wavelengths (Fig. S6F), with significantly lower UV reflectance (as represented by PC2, Fig. S6C, E, Table 3). Beach scrub lizards were characterized by brighter dewlaps than coppice lizards (PC1), and also more convex curves, i.e. slightly higher UV and red reflectance (as represented by higher PC3 scores), than lizards from the other two habitats (Fig. S6C, E, Table 3).

782
783 On Long Island the three habitats were relatively well discriminated (Fig. S7D). Importance
784 profiles indicated that short wavelengths were used to discriminate between beach scrub and man-
785 grove lizards (Fig. S7F). Beach scrub lizards had more curved reflectance profiles than in either of
786 the two other habitats, with higher levels of UV and red reflectance relative to intermediate wave-
787 lengths (PC3, Fig. S7C, E, Table 3). Beach scrub lizards also differed from mangrove lizards along
788 PC4 (Fig. S7E), which represented a rather small portion of the variance not already explained
789 by the first three principal components, and is therefore difficult to interpret (Fig. S7C). Coppice
790 lizards were significantly darker than mangrove and beach scrub lizards (PC1, Fig. S7C, E, Table
791 3).

792
793 On North Andros, although the random forest classification was significant ($P = 0.0216$, Table
794 1) and the average confusion matrix indicated that lizards from beach scrub were particularly well
795 predicted (Fig. S8D), no significant univariate differences were detected along any of the four PCs
796 (Fig. S8E, Table 3). Importance analysis of full-spectrum random forests showed higher impor-
797 tance scores near the UV-end of the spectrum in discriminating beach scrub dewlaps from the rest
798 (Fig. S8F). Besides, reflectance curves of beach scrub dewlaps appeared more similar to each other
799 in the UV range than dewlaps from other habitats (Fig. S8B), suggesting that the machines may
800 have used this low within-habitat variance, as opposed to between-habitat differences in means,
801 to correctly classify beach scrub lizards. A small sample size on this island may also have con-
802 tributed to a lack of power in detecting univariate differences using analyses of variance (Table S1).

803
804 On South Andros beach scrub and coppice dewlaps could be discriminated better against
805 each other than with mangrove dewlaps (Fig. S10D), with importance profiles supporting UV-
806 reflectance as a predictor of coppice lizards (Fig. S10F). Coppice lizards had more curved re-
807 flectance profiles than beach scrub lizards (PC3), and lizards from both habitats differed along
808 PC4, which is again more difficult to interpret (Fig. S10C, E, Table 3). Beach scrub lizards also
809 differed from mangrove lizards in PC4 (Fig. S10C, E, Table 3).

810
811 Classification success was not significantly better than expected by chance on Ragged Island
812 (Table 1) where nearly no habitat could be differentiated from any other based on reflectance.
